Introduction

The Reading Nook is a medium sized bookstore and café chain with locations spread across the Greater Toronto and Hamilton Area. As part of their efforts to modernize their technological stack, we have been contracted to migrate their existing inventory website into the cloud.

The organization's current inventory website consists of a Next.js frontend, a flask-based REST API, and a PostgreSQL database for persistent storage. These services are already deployed using containers however, for this project, the Reading Nook website team ask that we develop and implement a GitHub Actions CI/CD pipeline to build, store, and deploy each service to AWS incorporating ECR whenever a source commit occurs.

System Overview

The Reading Nook incorporates three primary components to create a functioning web application:

- Frontend: The user interface developed using Next.js for users to view and interact with inventory data.
- Backend: Implements Flask-based REST API to process client request and retrieve, add, update, and delete book records.
- Database: Data is handled by a PostgresSQL database hosted on Amazon RDS, storing information on book inventory.

Application components are containerized using Docker and deployed using Amazon Elastic Container Service (Amazon ECS). Container images are stored in Amazon Elastic Container Registry (Amazon ECR), allowing versioning and deployment. An Application Load

Balancer is used to distribute incoming traffic to the appropriate services, ensuring high availability and scalability.

A CI/CD pipeline is implemented using GitHub Actions. This pipeline automatically builds Docker images, pushes them to ECR, and updates the running services in ECS whenever changes are committed to the source repositories.

Architectural Diagram

Design Decisions

Amazon ECS with Fargate was used to run the containerized services without needing to deal with servers directly. This cuts down on setup and maintenance and also lets the frontend (Next.js) and backend (Flask API) run as separate services so they can be deployed and scaled independently.

Amazon ECR was used to store Docker images for both services. Keeping everything inside AWS makes deployments faster and avoids having to deal with external registries or extra authentication setup.

A CI/CD pipeline was built using GitHub Actions. Every time code is pushed, new Docker images are built, pushed to ECR, and deployed to ECS using rolling updates. This keeps deployments consistent and avoids having to manually update anything.

Application Load Balancers were set up to handle incoming traffic and route it to the correct containers. They also run health checks, so if something goes down, traffic is automatically redirected without needing manual intervention.

The system is deployed across multiple availability zones to improve reliability. Right now, the services are running with a low task count, but the setup supports scaling across zones if needed for better redundancy.

Amazon RDS for PostgreSQL was used for the database. It handles things like backups, patching, and general maintenance, which saves time, and it's placed in private subnets, so it isn't directly exposed to the internet.

AWS Secrets Manager is used to store database credentials instead of hardcoding them. This makes things more secure and allows credentials to be changed without rebuilding or redeploying the app.

Amazon CloudWatch with Container Insights is used for logging and monitoring. It gives visibility into how the services are running and makes it easier to catch and debug issues.
